Abstract
Air pollution is a high priority global health concern. The health damaging effects of ambient particulate matter (PM), a component of air pollution, are extensively documented, with 1.4% of deaths worldwide resulting from exposure to PM. A growing body of evidence suggests that mineral dust, found in PM, may contribute to some of these deleterious health impacts. Approximately half of atmospheric mineral dust originates from the Sahara Desert. This systematic but concise review summarizes the findings from recent literature exploring the adverse health effects of Saharan dust particles worldwide. The authors have shown that 1) PM contributes to all-cause and cause-specific mortality and morbidity; 2) the PM arising from Saharan dust contributes to excess all-cause and cause-specific mortality and morbidity; and 3) larger particle sizes may be more harmful than smaller particle sizes. However, there remain many questions regarding their effects on vulnerable patient populations, underlying mechanisms of action, and regional variations in both environmental and health effects. This review highlights the urgent need for continued and deeper analyses of this emerging public health issue. Int J Occup Med Environ Health. 2019;32(6)

air pollution, particulate matter, public health, dust, Africa, Northern Africa

INTRODUCTION
The World Health Organization (WHO) regards air pollution as a top global health priority [1]. The adverse effects of particulate matter (PM), a component of air pollution, on human health are well documented. The WHO estimates that 1.4% of all deaths worldwide result from exposure to PM [2]. One of the components of PM, atmospheric mineral dust, has recently attracted attention since it may be responsible for some of the hazardous effects of PM [3]. The main source of atmospheric mineral dust is from the desert, with approximately half originating from the Sahara Desert [3], although dust also spreads from other regions including the Arabian Peninsula, Central Asia, China, Australia, America, and South Africa. Each year, 1–3 gigatons of dust are emitted from these regions [4]. Sand and dust storms frequently occur in semi-arid and...
In this short review, the authors have summarized the findings presented in recent literature exploring the association between Saharan dust particles and human health, with a view to collating the available evidence and establishing areas of research that require further effort in order to better understand and eventually tackle this important domain.

METHODS

The Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines were followed [6]. The authors searched the PubMed database using the terms “Saharan dust” OR “desert dust” AND “health.” Studies selected for this review (after removing duplicates) were limited to those conducted on humans and written in English, and the final search took place on May 20, 2019. The search scheme is presented in Figure 1.

RESULTS

Nineteen studies specifically investigated the health impacts of Saharan dust exposure on human health, as summarized in Table 1. Of these, 17 examined populations in Southern Europe, specifically in the Mediterranean basin, which experiences proven increases in the ambient PM levels recorded in air quality monitoring networks from Saharan dust, due to proximity to the Sahara and atmospheric dynamics [7]. Two studies focused on Caribbean populations [8,9]. All studies were epidemiological studies using a mixture of analytical techniques but mainly time-series analyses. Primary endpoints were mainly all-cause mortality or cause-specific (cardio-respiratory) mortality, or, for those studies examining emergency admissions to hospital, either hospital admission rates [10–14] or asthma attacks [8,9]. Since the effects of air-borne particles are related to their chemical composition and size, some studies investigated associations between health outcomes and different particle sizes but all studies included the coarse fraction (i.e., PM between 2.5 and 10 μm, PM_{10-2.5}).
The results can be summarized as follows. First, in general, PM levels were associated with an increased risk of all-cause and cause-specific mortality, whether of desert or non-desert origin [11,12,15–19]. In the studies examining hospital admissions or disease-specific outcomes, a similar trend was seen, with increased PM concentrations associated with increased numbers of hospitalizations [10,12] or hospital-treated asthma attacks [8,9]. Therefore, PM levels, whether of desert or non-desert origin, appear to have an impact on general and respiratory health.

Second, most but not all studies detected effects on outcomes attributable to the Saharan dust component of the detected PM. These effects tended to be stronger for cause-specific outcomes, i.e., those related to cardiovascular and respiratory morbidity. For example, Tri-anti et al. [13] observed that desert dust days were associated with higher numbers of ER visits for asthma, chronic obstructive pulmonary disease and respiratory infections, with increases of 38%, 57% and 60%, respectively (p < 0.001), while Staffoggia et al. [12] detected similar associations of mortality and hospitalizations with increases in desert and non-desert PM$_{10}$, but stronger associations with desert dust for cardiovascular mortality (1.10%, 95% CI: 0.16–2.06 compared with 0.49%; 95% CI: 0.31–1.29 for non-desert dust).

Similarly, Reyes et al. [11] reported that while periods without Saharan dust intrusions were marked by a statistically significant association between daily mean PM$_{2.5}$ concentrations, and all- and circulatory-cause hospital admissions, periods with such intrusions saw a significant

increase in respiratory-cause admissions, associated with fractions corresponding to PM$_{10}$ and PM$_{10-2.5}$. Alessandri-ni et al. [10] saw an effect modification of Saharan dust on the association between hospitalizations and particles for respiratory diseases and cerebrovascular diseases. Perez et al. [16], Mallone et al. [20], and Middleton et al. [19] in particular detected an excess risk of cardiovascular events on Saharan dust days compared to non-dust days. In a study of children admitted with asthma in Guadeloupe, Caribbean [9], there were excess risk percentages for visits related to asthma on days with dust compared to days without dust (9.1% [95% CI: 7.1–11.1] vs. 1.1% [95% CI: 25.9–4.6] for PM$_{10}$, and 4.5% [95% CI 2.5–6.5] vs. 1.6% [95% CI 21.1–3.4] for PM$_{2.5-10}$). However, these results were not consistent, with Samoli et al. [18] detecting a negative correlation between particle effects and mortality during dust events. Nevertheless, most of the available evidence appears to suggest that PM composed of Saharan dust contributes to excess adverse health outcomes.

The third major observation from the collated studies is that particle size has an impact on the observed health effects. Several studies observed significant impacts on all-cause or cause-specific mortality for PM$_{10}$ (but not PM$_{2.5}$ or PM$_{10-2.5}$ [21]) and PM$_{10-2.5}$ (but not PM$_{2.5}$ [15,22]). Coarser particle sizes appear to have a greater impact on mortality than smaller particle sizes.

However, not all studies have reported the same pattern of findings. In individuals living in Gran Canaria Island, Spain, elevated Saharan dust levels did not exacerbate allergies in adult and elderly patients, as assessed by the number of ER admissions, medication needs, and pulmonary function [14].

CONCLUSIONS

There are several theories on the mechanism underlying the impact of Saharan dust on human health. As a component of PM, dust particles may be inhaled. Accordingly, the particle size has been proposed as a determinant of the potential of Saharan dust to cause health-related damage. Particles > 10 μm are generally not respirable, so the deleterious impacts of very coarse particles are likely to be external, for example, by irritating the skin and eyes. Particles < 10 μm (PM$_{10}$) in diameter, however, can be inhaled [4] and are, therefore, associated with respiratory disorders, given their direct contact with the upper respiratory tract. The smallest particles may enter the lower respiratory tract and eventually the bloodstream, thereby exerting lower respiratory and cardiovascular effects.

Details of the molecular and cellular events underlying the interaction of these particles with physiological systems are scarce. Non-desert dust particulate matter and other air pollutants are known to cause molecular and cellular alterations, for example, aberrant gene expression from exposure to particulate matter in general and anthropogenic pollutants specifically [23–26]. Such testing began at the bench using animal models and is now entering the clinical domain. Understanding how desert dust exposure interacts with specific tissues and cell populations at the molecular level could shed light on other health-damaging effects of dust exposure, deepen our knowledge of dust exposure beyond the effects based on the particle size, and provide opportunities for predictive tests or exposure biomarkers.

An interesting hypothesis is that infectious diseases disseminated through dust dispersion may also be responsible for adverse health effects. One way in which this might occur is that dust inhalation may damage protective mucosae, rendering individuals susceptible to bacterial infection [4]. Microbial populations and anthropogenic pollutants have been shown to travel on dust [3] and may contribute to outbreaks of infectious diseases such as meningitis [27], and some studies support this theory [28,29].

One study compared the atmospheric microbiome on dust-affected and dust-free days by applying modern ge-
Finally, Skonieczny et al. [35] recently reconstructed Saharan dust deposition > 240,000 years and in doing so demonstrated that present-day Saharan dust deposition is elevated compared to 5000–11,000 years ago. During that time, decreased dust in Saharan plumes may have contributed to the development of monsoon rains, and the effect of dust may continue to impact on climatic change [35]. An in-depth understanding of Saharan dust deposition, its environmental impact, and its health-related sequelae may not only be relevant but also increasingly urgent as both a public health and environmental concern.

In collating the available evidence in this mini-review, the authors have shown that 1) PM contributes to all-cause and cause-specific mortality and morbidity; 2) the PM arising from Saharan dust contributes to excess all-cause and cause-specific mortality and morbidity; and 3) larger particle sizes may be more harmful than smaller particle sizes. Several associations exist between Saharan dust exposure and adverse health outcomes. As a PM component, Saharan dust is respirable and, as expected [2,3], reportedly increases respiratory hospitalizations in patients with asthma, allergic disorders, and other respiratory diseases [8–11, 16, 36, 37]. The theorized association with cardiovascular illness [4] has been demonstrated in a subset of studies that show an increase in mortality due to cardiovascular causes upon dust exposure [20, 21, 38]. While the evidence supporting a health impact of Saharan dust exposure is emerging and fairly robust, the mechanisms underlying these associations remain elusive and require further study, perhaps by assessing blood-borne molecules, such as through gene expression or metabolite analyses, on Saharan dust days.
